9 Abstract

When researchers carry out a null hypothesis significance test, it is tempting to assume that a statistically significant result lowers $\text{Prob}(H_0)$, the probability of the null hypothesis being true. Technically, such a statement is meaningless for various reasons: e.g., the null hypothesis does not have a probability associated with it. However, it is possible to relax certain assumptions to compute the posterior probability $\text{Prob}(H_0)$ under repeated sampling. We show in a step-by-step guide that the intuitively appealing belief, that $\text{Prob}(H_0)$ is low when significant results have been obtained under repeated sampling, is in general incorrect and depends greatly on: (a) the prior probability of the null being true; (b) Type I error, and (c) Type II error. Through step-by-step simulations using open-source code in the R System of Statistical Computing, we show that uncertainty about the null hypothesis being true often remains high despite a significant result. To help the reader develop intuitions about this common misconception, we provide a Shiny app (<https://danielschad.shinyapps.io/probnull/>). We expect that this tutorial will be widely useful for students and researchers in many fields of psychological science and beyond, and will help researchers better understand and judge results from null hypothesis significance tests.

Keywords: Null hypothesis significance testing, Bayesian inference, statistical power

Null hypothesis significance testing (NHST), as it is practised in all areas of science, involves a fairly straightforward procedure. We begin by positing a null hypothesis H_0 , usually a point null hypothesis that a parameter μ has a specific value: $H_0 : \mu = \mu_0$. Then we collect data, compute the sample mean \bar{x} , and estimate the standard error SE from the sample standard deviation s and sample size n by computing $SE = s/\sqrt{n}$. Next, we

1 compute some statistic such as the observed t-statistic, $t_{observed} = \frac{\bar{x} - \mu_0}{SE}$. If the absolute
 2 value of the observed t-statistic is larger than the absolute value of some critical t-value, we
 3 reject the null hypothesis. Usually we also compute the p-value, which is the probability of
 4 obtaining the observed t-statistic, or a value more extreme, assuming that the null hypothe-
 5 sis is true. Conventionally, when the p-value is less than 0.05, we reject the null hypothesis.
 6 A common phrasing is to say that we have a “statistically significant” result, and that the
 7 effect of interest is “reliable.” As is well known, an issue that is of great importance here is
 8 false and true discovery rates (Betancourt, 2018).

9 The false discovery rate is the probability of incorrectly rejecting the null when the
 10 null is in fact true; this is referred to as Type I error. It is conventionally fixed at 0.05.
 11 The true discovery rate is the probability of correctly rejecting the null when μ has some
 12 specific point value that is not the null value μ_0 ; this is usually called power. The quantity
 13 (1-power) is called Type II error, often written as β ; it is the probability of incorrectly
 14 accepting the null when it is false with some specific value for μ , i.e., when the true μ is
 15 some specific point value other than μ_0 .

16 It is well-known that power needs to be high in order to draw inferences correctly
 17 from a statistically significant result; when power is low, statistically significant results are
 18 *guaranteed* to be overestimates or even to have the wrong sign (Gelman & Carlin, 2014),
 19 and they are likely to be unreplicable (Vasishth, Mertzen, Jäger, & Gelman, 2018). In other
 20 words, a significant result under low power is *never* “reliable” in any sense of the word.

21 Researchers sometimes assume that a significant result reduces *the probability of the*
 22 *null hypothesis being true* to a low value. For example, a survey by Tam et al. (2018) reports
 23 this widespread misunderstanding of the p-value by medical doctors. As they put it:

24 Many respondents conceptualised the P value as numerically indicating the nat-
 25 ural probability of some phenomenon — for instance, a 95% or 5% chance of
 26 the truth or falsity of a hypothesis in the real world.

27 A second example comes from Doherty, Benson, and Higham (2002). On page 376,

1 Table 2, they state that “[the p-value] is the probability that the null hypothesis is true.”
 2 A third example comes from a textbook written for medical researchers (Harris & Taylor,
 3 2003). On their page 24, they write: “The P value is used when we wish to see how likely it
 4 is that a hypothesis is true”; and on page 26, they write: “The P value gives the probability
 5 that the null hypothesis is true.”

6 Here, we investigate the posterior probability of the null hypothesis being true under
 7 different possible assumptions. Specifically, when power is low, medium, or high, and when
 8 Type I error is 0.05, 0.01, or 0.005.

9 Intuitively, it does seem obvious that rejecting the null hypothesis after finding a
 10 significant result leads us to belief that the posterior probability of the null hypothesis
 11 being true is low. We will show in this paper that this intuitive belief is in general wrong,
 12 except in two extreme situations that are rarely or never realized: when statistical power is
 13 high (greater than 0.80) and Type I error is low (0.005).

14 Note that, technically, talking about “the probability that the null hypothesis is true”
 15 is meaningless in the NHST framework. Probability mass functions can only be associated
 16 with discrete outcomes that constitute a random variable. An example from everyday life
 17 would be the probability of catching a train when running late: there are two possible
 18 outcomes, either one gets the train or not, and each outcome has a probability associated
 19 with it. By contrast, the null hypothesis is not a random variable and therefore cannot
 20 have a probability associated with the two possible outcomes of being true or false. The
 21 null hypothesis is either true or it is false.

22 However, in order to talk about the probability of the null hypothesis being true or
 23 false, we can assume for the moment that the null hypothesis is a random variable. Suppose
 24 that before running the experiment, we begin with the assumption that the null hypothesis
 25 is believed to be true with some probability θ_{prior} . Once we get a significant result, the
 26 probability of the null being true should (intuitively) fall to some low value $\theta_{posterior}$.

27 But these point values θ_{prior} and $\theta_{posterior}$ only partly characterize our beliefs. Before
 28 running the experiment, we surely have some uncertainty about the probability θ_{prior} that

the null is true. For example, the null may be true at the outset with probability somewhere between 85 and 95%. Thus, the prior probability of the null being true has a probability *distribution* associated with it, it cannot be just a *point* value. Still relying on intuition, we might say that a statistically significant result should shift this probability distribution to some low range, say 10-20%. Such a hypothetical situation is visualized in Figure 1a.

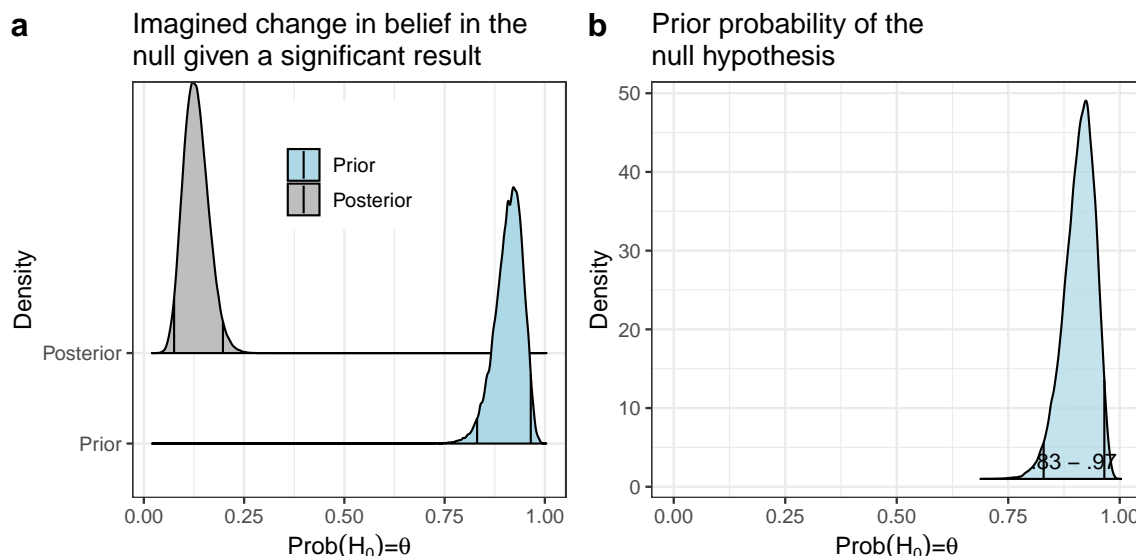

Figure 1. Prior and posterior probability of the null hypothesis. a) An illustration of how our belief in the null hypothesis—expressed as a probability distribution— might hypothetically shift once we see a statistically significant result. The vertical lines show the 95% credible intervals. b) Prior probability of the null hypothesis being true, expressed as a Beta(60,6) distribution.

To summarize, strictly speaking, the null hypothesis is either true or false, it has no probability distribution associated with it. So, one cannot even talk about the probability of the null hypothesis being true. Nevertheless, it is possible to relax this strict stipulation and ask ourselves: how strongly do we believe that the null is true before and after we do a significance test? A domain expert working in a particular field should be able to state, as a probability distribution, his or her a priori confidence level in a particular null hypothesis. In practice, some expert elicitation might be required (Oakley & O’Hagan, 2010; O’Hagan et al., 2006).

Bayes’ rule allows us to calculate this posterior probability of the null hypothesis being

1 true. Bayes' rule states that, given a vector of data y , we can derive the probability density
 2 function of a parameter or a vector of parameters θ given data, $f(\theta | y)$, by multiplying
 3 the likelihood function of the data, $f(y | \theta)$, with the prior probability of the parameter(s),
 4 $f(\theta)$, and dividing by the marginal likelihood of the data, $f(y)$:

$$f(\theta | y) = \frac{f(y | \theta)f(\theta)}{f(y)} \quad (1)$$

5 The marginal likelihood of the data can be computed by integrating out the param-
 6 eter(s) θ :

$$f(y) = \int f(y, \theta) d\theta = \int f(y | \theta)f(\theta) d\theta \quad (2)$$

7 As McElreath (2016) mentions, Bayes' rule can be used to work out the posterior
 8 probability of the null being true given a significant effect under repeated sampling. This
 9 is what we turn to next. Before we can carry out this computation, we have to decide on
 10 the prior probability of the null hypothesis being true; this is not too difficult to determine
 11 for specific research questions. We could start by eliciting from a researcher their prior
 12 belief about the probability of some particular null hypothesis being true: $Prob(H_0 \text{ true})$.
 13 Given such a prior probability for the null hypothesis, we then stipulate a Type I error,
 14 $Prob(sig|H_0 \text{ true}) = \alpha$ and a Type II error, $Prob(not \text{ sig}|H_0 \text{ false}) = \beta$. (When we write
 15 $H_0 \text{ false}$, we mean that the null is false with some specific value for the parameter μ). Once
 16 we have these numbers, Bayes' rule allows us to compute $Prob(H_0 \text{ true}|sig)$, the posterior
 17 probability of the null being true given a significant result under repeated sampling. In
 18 other words, Bayes' rule helps us quantify the extent to which our prior belief should shift
 19 in the light of the long-run probability of obtaining a statistically significant result:

$$Prob(H_0 \text{ true}|sig) = \frac{Prob(sig|H_0 \text{ true}) \times Prob(H_0 \text{ true})}{Prob(sig)} \quad (3)$$

20 The denominator $Prob(sig)$ is the marginal probability of obtaining a significant

1 effect under repeated sampling, and is straightforward to compute using the law of total
 2 probability (Kolmogorov, 2018). This law states that the probability of a random variable Z ,
 3 $Prob(Z)$, given another random variable A , is $Prob(Z|A)Prob(A) + Prob(Z|\neg A)Prob(\neg A)$.
 4 Translating this to our particular question, the event Z is the significant effect we obtained
 5 under repeated sampling, and the event A is the null hypothesis being true or false.

$$\begin{aligned}
 Prob(sig) &= Prob(sig|H_0 \text{ true})Prob(H_0 \text{ true}) + Prob(sig|H_0 \text{ false})Prob(H_0 \text{ false}) \\
 &= \alpha \times Prob(H_0 \text{ true}) + (1 - \beta) \times (1 - Prob(H_0 \text{ true})) \\
 &= \alpha \times \theta + (1 - \beta) \times (1 - \theta)
 \end{aligned} \tag{4}$$

6 The last line above arises because $Prob(sig|H_0 \text{ true}) = \alpha$ (Type I error),
 7 $Prob(sig|H_0 \text{ false}) = 1 - \beta$ (power), and $Prob(H_0 \text{ true}) = \theta$ (the prior probability of
 8 the null being true).

9 Thus, $Prob(H_0 \text{ true}|sig)$ is really a function of three quantities:

- 10 1. The false discovery rate, or Type I error α .
- 11 2. The true discovery rate, or power $(1 - \beta)$, where β is Type II error.
- 12 3. The prior probability of null being true (θ).

13 We will now compute, under different assumptions, the posterior probability of the
 14 null being true given a significant effect. Before we can do this, we have to decide on a
 15 prior probability of the null hypothesis being true. What is a reasonable prior distribution
 16 to start with? In a recent paper, Benjamin et al. (2018) write the following: “Prediction
 17 markets and analyses of replication results both suggest that for psychology experiments,
 18 the prior odds of H_1 relative to H_0 may be only about 1:10. A similar number has been
 19 suggested in cancer clinical trials, and the number is likely to be much lower in preclinical
 20 biomedical research.” A prior odds of 1:10 of the alternative being true relative to the null
 21 means that the probability of the null being true is about 90%. We take this estimate as

1 a starting point; below we will also consider alternative scenarios where the probability of
 2 the null being true is lower.

3 For now, we will assume that the null hypothesis H_0 has the high prior probability
 4 of 90% of being true. Just as a coin has heads and tails as possible outcomes, the null
 5 hypothesis can have two possible outcomes, true or false, each with some probability. Thus,
 6 we can now talk about the probability θ of the null hypothesis being true. We can model
 7 this by assuming that a success or failure is generated from a Bernoulli process that has
 8 probability of success θ :

$$H_0 \sim \text{Bernoulli}(\theta) \quad (5)$$

9 Because our prior belief that the null is true will come with some uncertainty (it is
 10 not merely a point value), we can model this prior belief through a Beta distribution. For
 11 example, a prior $\text{Beta}(60, 6)$ on θ expresses the assumption that the prior probability of
 12 the null being true is between 0.83 and 0.97 with probability 95% (approximately), with
 13 mean probability approximately 0.90. The lower and upper bounds of the 95% credible
 14 interval can be computed using the inverse cumulative distribution function of the Beta
 15 distribution. We simply solve the integrals for the lower and upper bounds:

$$\int_{-\infty}^{\text{lower}} f(x)dx = \int_{-\infty}^{\text{lower}} \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} x^{a-1}(1-x)^{b-1} dx = 0.025 \quad (6)$$

16 and

$$\int_{-\infty}^{\text{upper}} f(x)dx = \int_{-\infty}^{\text{upper}} \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} x^{a-1}(1-x)^{b-1} dx = 0.975 \quad (7)$$

17 The mean can be computed from the fact that a random variable X that is generated
 18 from a Beta distribution with parameters a and b has mean:

$$E[X] = \frac{a}{a+b} \quad (8)$$

1 Given the a and b parameters, the mean is:

$$E[X] = \frac{a}{a+b} = \frac{60}{60+6} = 0.9 \quad (9)$$

2 Figure 1b visualizes this prior probability of the null hypothesis being true.

3 Given this prior probability density function Beta(60,6) for θ , we are now in a position
 4 to investigate how the posterior probability of the null being true changes under different
 5 assumptions. We can use Monte Carlo sampling to compute the posterior probability of H_0
 6 being true given significant results under repeated sampling:

7 1. Fix α (Type I error) and β (Type II error).

8 2. Do 100,000 times:

9 (a) Sample one value θ from the Beta(60,6) distribution.

10 (b) Compute posterior probability of θ given α, β , and the sampled value of θ from
 11 the prior distribution Beta(60,6):

$$\alpha \times \frac{\theta}{(\alpha \times \theta + (1 - \beta) \times (1 - \theta))} \quad (10)$$

12 (c) Store this posterior probability of the null hypothesis being true.

13 3. Plot the distribution of the stored probabilities, or display summary statistics such as
 14 the mean and the 95% credible interval.

15 There are two interesting cases. The first is when statistical power is low (mean:
 16 10%); we will show that in this case, it simply doesn't matter much if we get a significant
 17 result. The posterior probability of the null being true will not change substantially; this is
 18 regardless of whether Type I error is 0.05 or some lower value like 0.005, as recommended
 19 by Benjamin et al. (2018). Note that here, when we say that the posterior probability of
 20 the null doesn't change substantially, we are not talking about the mean of the posterior
 21 probability; rather, we are more interested in the 95% credible interval, which represents the

1 uncertainty of the posterior probability. Thus, even if the mean of the posterior distribution
 2 is numerically lower than the mean of the prior distribution, if the uncertainty associated
 3 with the posterior distribution is high, the prior-to-posterior change in mean probability is
 4 not really meaningful.

5 The other case is where statistical power is high (mean: 90%); here, the posterior
 6 probability of the null being true will change considerably once we have a significant result
 7 under repeated sampling, especially if we follow the recommendation of Benjamin et al.
 8 (2018) to lower Type I error to 0.005.

9 Anticipating our main conclusion, when the prior probability of the null being true is
 10 low, the only situation where a statistically significant effect under repeated sampling can
 11 shift our belief substantially against the null hypothesis being true is when statistical power
 12 is high. When power is low, it simply doesn't matter whether you lower the Type I error
 13 to 0.005, as suggested by Benjamin et al. (2018) and others. Null hypothesis significance
 14 testing only makes sense if power is high; in all other situations, the researcher is wasting
 15 their time computing p-values. When power is low, the intuition, that a significant result
 16 will lead to a low posterior probability of the null hypothesis being true, is an illusion.

17 **Case 1: Investigating the posterior probability of the null hypothesis being**
 18 **true when power is low (Type II error 0.90) and the prior probability of the**
 19 **null hypothesis is high (Mean Prob(H0)=.90)**

20 We next look at the posterior probability for different situations: As a first case,
 21 we investigate the posterior probability of the null hypothesis being true when the prior
 22 probability of the null hypothesis is high (Mean Prob(H0)=.90) and when power is low
 23 (Type II error 0.90). We investigate several scenarios by using different Type I errors
 24 ($\alpha = 0.05, 0.01$ and 0.005).

25 *Scenario 1: Low power (0.10), Type I error 0.05.* Let Type I error be $\alpha =$
 26 0.05 and Type II error be $\beta = 0.90$. So, we have power at $1 - \beta = 0.10$. Such low power is
 27 by no means an uncommon situation in areas like cognitive psychology, psycholinguistics,

Figure 2. Probabilities for the Null-hypothesis, $P(H_0) = \theta$. Prior probability (blue) and posterior probabilities given a significant effect (grey) at a Type I error threshold α of 0.05 and 0.01. This is shown for a situation of low statistical Power of 10% (Type II error rate $\beta = 90\%$) and with a high prior probability for the null hypothesis ($\theta \sim \text{Beta}(60, 6)$; blue).

1 and linguistics; examples from psycholinguistics are discussed in Jäger, Engelmann, and
 2 Vasishth (2017); Nicenboim, Roettger, and Vasishth (2018); Vasishth et al. (2018).

3 Figure 2 shows the prior and posterior distributions. The prior distribution is plotted
 4 in blue. Figure 2 shows that getting a significant result hardly shifts our belief regarding
 5 the null. This should be very surprising to researchers who believe that a significant result
 6 shifts their belief about the null hypothesis being true to a low value. Next, consider what
 7 happens when we reduce Type I error to 0.01, which is lower than the traditional 0.05.

8 **Scenario 2: Low power (0.10), Type I error 0.01.** Many researchers (Ben-
 9 jamin et al., 2018) have suggested that lowering Type I error will resolve many of the
 10 problems with NHST. Let's start by investigating what changes when we decrease Type I

1 error to 0.01 (researchers like Benjamin et al., 2018 have proposed 0.005 as a threshold for
2 Type I error; we turn to this proposal below). Type II error is held constant at 0.90.

3 Figure 2 shows that lowering Type I error does shift our posterior probability of the
4 null being true a bit more but not enough to have any substantial effect on our beliefs. It
5 seems unreasonable to discard a null hypothesis if the posterior probability of it being true
6 lies between 30 and 70%.

7 ***Scenario 3: Low power, Type I error 0.05, incorporating uncertainty about***
8 ***Type II error.*** So far, we have been assuming a point value as representing power.
9 However, power is really a function that depends (inter alia) on the magnitude of the true
10 (unknown) effect. Power therefore also has some uncertainty associated with it, because
11 we do not know the magnitude of the true effect, and we do not know the true standard
12 deviation. We can introduce uncertainty about power (or equivalently, uncertainty about
13 Type II error) into the picture by setting our prior on $\beta \sim \text{Beta}(10, 4)$, so that the Type II
14 error is around 70%. Different levels of power (1-Type II error) are visualized in Figure 3,
15 and the low power situation of 30% is shown in the bottom row of the figure.

16 Incorporating the uncertainty about Type II error (equivalently, power) increases
17 the uncertainty about the posterior probability of the null quite a bit. Compare Figure 2
18 ($\alpha = 0.05$) and Figure 4a (low power). Figure 4a shows that the posterior of the null being
19 true now lies between 40 and 90% (as opposed to 70 and 90% in Figure 2).

20 ***Scenario 4: Type I error 0.01, incorporating uncertainty in Type II error.***
21 Having incorporated uncertainty into Type II error, consider now what happens if we lower
22 Type I error to 0.01, from 0.05. Figure 4d shows (cf. low power) that now the posterior
23 distribution for the null hypothesis shifts to the left quite a bit more, but with wide uncer-
24 tainty (10-60%). Even with a low Type I error of 0.01, we should be quite unhappy rejecting
25 the null if the posterior probability of the null being true is between the wide range of 10
26 and 60%.

27 ***Scenario 5: Type I error 0.005, incorporating uncertainty in Type II error.***
28 Next, consider what happens if we lower Type I error to 0.005. This is the suggestion from

Figure 3. Visualization of the probability distribution associated with Type II error β corresponding to low power ($\beta \sim \text{Beta}(10, 4)$, mean power $E[1 - \theta] = 30\%$), medium power ($\beta \sim \text{Beta}(8, 8)$, mean power $E[1 - \theta] = 50\%$), and high power ($\beta \sim \text{Beta}(2, 20)$, mean power $E[1 - \theta] = 90\%$). Recall that Power is 1-Type II error.

- 1 Benjamin et al. (2018). Perhaps surprisingly, Figure 4g shows that now the posterior
- 2 distribution for the null hypothesis does not shift much compared to Scenario 4 (see Fig.
- 3 4d): the range is 6 to 45% (compare with the range 10-60% in scenario 4). Thus, when
- 4 power is low, there is simply no point in engaging in null hypothesis significance testing.
- 5 Simply lowering the threshold of Type I error to 0.005 will not change much regarding our
- 6 belief in the null hypothesis.

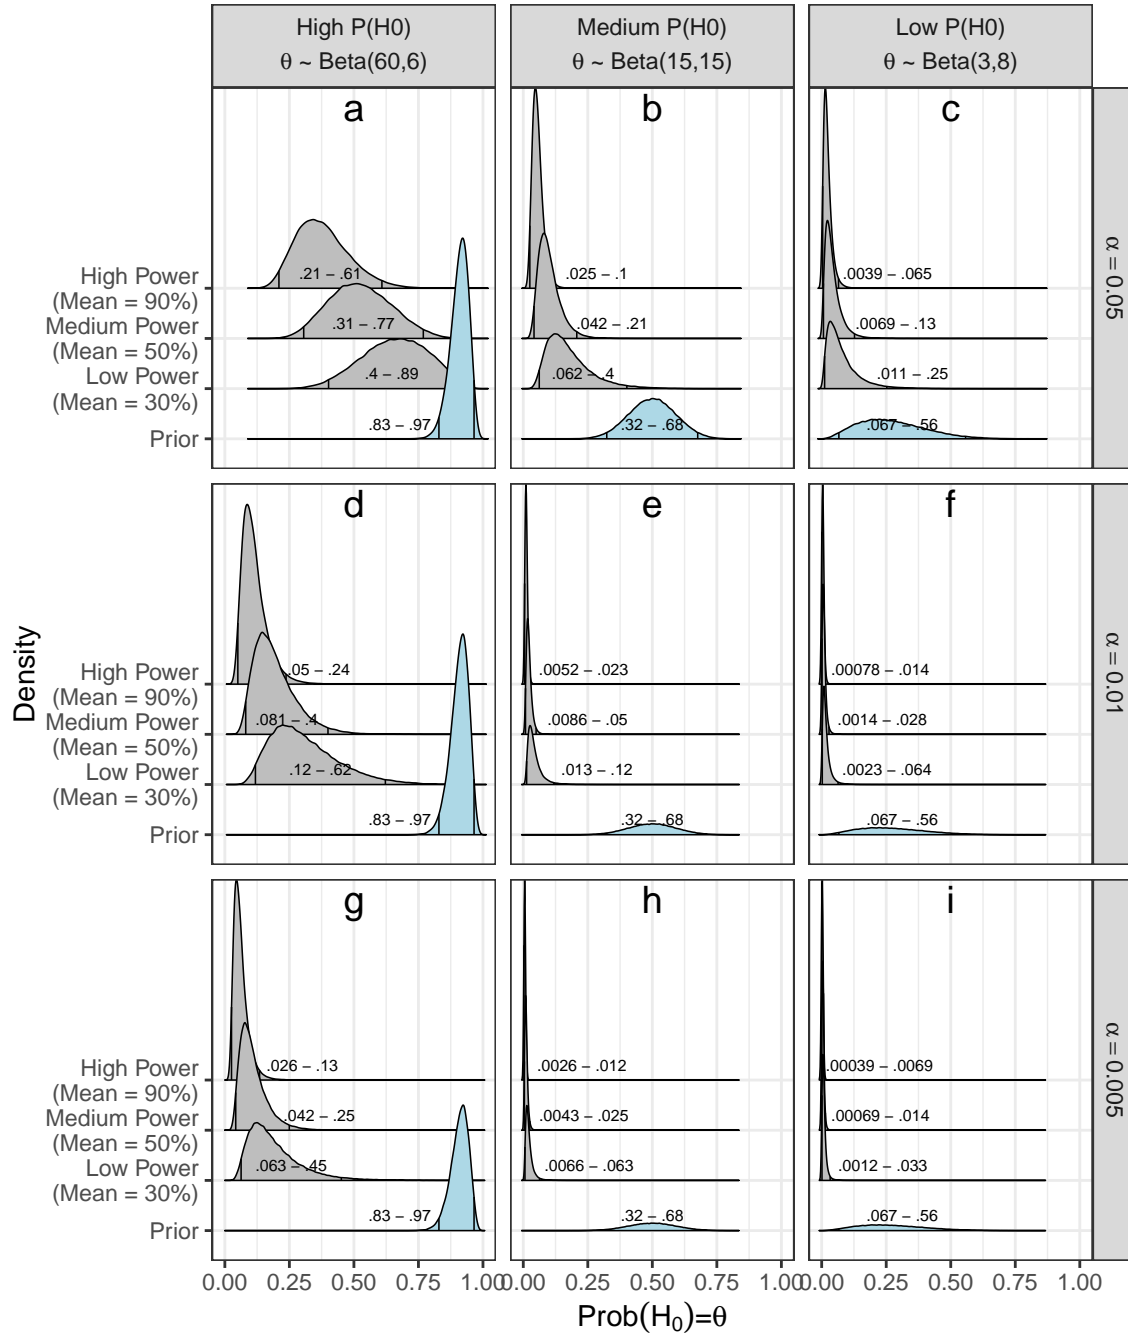

Figure 4. Probabilities for the null hypothesis, $P(H_0) = \theta$, considering uncertainty about power. Prior probability (blue) and posterior probabilities given a significant effect (grey) at a Type I error α of 0.05 (upper panels), 0.01 (middle panels), and 0.005 (lower panels). This is shown for situations of low statistical Power, $\beta \sim \text{Beta}(10, 4)$ (mean Type II error rate of about $\beta = 70\%$, mean Power of about 30%), medium statistical Power, $\beta \sim \text{Beta}(8, 8)$ (mean Type II error rate of $\beta = 50\%$, mean Power of 50%), and high statistical Power, $\beta \sim \text{Beta}(2, 20)$ (mean Type II error rate of about $\beta = 10\%$, mean Power of about 90%), and for situations with a high (left panels), medium (middle panels), and low (right panels) prior probability for the null hypothesis.

Case 2: Investigating the posterior probability of the null hypothesis being true when power is high

As a second case, we investigate the posterior probability of the null hypothesis being true when power is high. We consider the case where power is around 90%. We will still assume a high prior probability for the null ($\text{Mean Prob}(H_0) = .90$). We will consider three scenarios: Type I error at 0.05, 0.01, and 0.005.

Scenario 6: High power (0.90), Type I error 0.05. First consider a situation where we have high power and Type I error is at the conventional 0.05 value. The question here is: in high power situations, does a significant effect shift our belief considerably away from the null, with Type I error at the conventional value of 0.05? The prior on Type II error is shown in Figure 3. The mean Type II error is 10%, implying a mean for the power distribution to be 90%. Perhaps surprisingly, Figure 4a shows that even under high power, our posterior probability of the null being true does not shift dramatically: the probability lies between 20 and 60%.

Simulation 7: High power (mean 0.90), Type I error 0.01. Next, we reduce Type I error to 0.01. Figure 4d shows that when power is high and Type I error is set at 0.01, we get a big shift in posterior probability of the null being true: the range is 5-25%.

Simulation 8: High power (mean 0.90), Type I error 0.005. Next, in this high-power situation, we reduce Type I error to 0.005. Figure 4g shows that when power is high and Type I error is set at 0.005, we get a decisive shift in posterior probability of the null being true: the range is now 2-13%.

Cases 3 and 4: Prior probability for the null is medium or low

Finally, we consider cases where the prior probability for the null is medium or low.

Low prior probability for the null: Mean Prob(H_0)=.10. One possible objection to the above analyses, however, is that the prior probability for the null hypothesis could often be much smaller than an average of 90%. Indeed, in some situations, the null hypothesis may be very unlikely. We here simulate a situation where the prior probability

1 for the null is an average of 10% ($\theta \sim \text{Beta}(3, 8)$). For this situation, Figures 4c,f, and i
 2 show that the posterior probability for the null is always decisively low. Even for a conven-
 3 tional Type I error of $\alpha = 0.05$ in a low-powered study, the posterior probability for the null
 4 ranges from 1 to 25%, which is quite low, and when turning to smaller α levels or higher
 5 power, the effect is decisive.

6 However, of course this is not very informative, as we started out assuming that the
 7 null hypothesis was unlikely to be correct in the first place. Thus, we haven't learned
 8 much; a statistical significance test would just confirm what we already believed with high
 9 certainty before we carried out the test.

10 ***Medium prior probability for the null: Mean Prob(H_0)=.50.*** Now consider
 11 the case where the prior probability for the null being true lies at an average of 50% (e.g.,
 12 $\theta \sim \text{Beta}(15, 15)$). Here, we don't know whether the null or the alternative hypothesis is
 13 true a priori, and both outcomes seem similarly likely. In this situation, when we use a
 14 conventional Type I error level of $\alpha = 0.05$ in a low-powered study, a significant effect will
 15 bring our posterior probability for the null only to a range of 6-40%, and will thus leave us
 16 with much uncertainty after obtaining a significant effect.

17 However, either using a stricter Type I error level (e.g., $\alpha = 0.005$) or running a
 18 high-powered study each suffices to yield informative results: For a high-powered study and
 19 $\alpha = 0.05$, a significant result will (under our assumptions) bring the posterior probability to
 20 2-10% (Figure 4b), which is quite informative. And for a Type I error level of $\alpha = 0.005$ a
 21 significant effect brings decisive evidence against the null for all the levels of power that we
 22 investigated (Figure 4h), with a posterior probability of 0.7-6% even for low-powered studies.
 23 This suggests that when the prior probabilities of the null and the alternative hypotheses
 24 are each at 50%, then either high power or a strict Type I error of $\alpha = 0.005$ will yield
 25 informative outcomes once a significant effect is observed.

Discussion

In summary, we analyzed the posterior probability for the null given a significant effect. We provide a shiny app (<https://danielschad.shinyapps.io/probnull/>) that allows the user to compute the posterior distribution for different choices of prior, Type I and Type II error. For psychology and preclinical biomedical research, the prior odds of H1 relative to H0 are estimated to be about 1:10 (Benjamin et al., 2018), reflecting a high prior probability of the null of 90%. For this common and standard situation in psychology and other areas, when power is low, the posterior probability of the null being true doesn't change in any meaningful way after seeing a significant result, even if we change Type I error to 0.005. What shifts our belief in a meaningful way is reducing Type I error to say 0.005 (as suggested by Benjamin et al., 2018 and others), *as well as* running a high powered study. Only this combination of high power and small Type I error rate yields informative results.

One might object here that we set the prior probability of the null hypothesis being true at an unreasonably high value. This objection has some merit; although typically the prior probability for the null may lie at 10%, there may well be some situations where the null is unlikely to be true a priori. In this situation, our results show that a significant effect does indicate a very low posterior probability of the null. This is the case across a range of Type I error levels (α of 0.05, 0.01, 0.005) and for different levels of power (Figure 4c+f+i). Even for low power studies with $\alpha = 0.05$ the posterior probability is between 1 and 25%, which is quite low. So yes, if the prior probability of the null being true is already low, even with relatively low power and the standard Type I error level of 0.05, we are entitled to changing our belief quite strongly against the null once we have a significant effect. An obvious issue here is that if we already don't believe in the null before we do the statistical test, why bother to try to reject the null hypothesis? Even if we were satisfied with rejecting a null hypothesis we don't believe in in the first place, running low power studies is always a bad idea because of Type M and S error. As Gelman and Carlin (2014) and many others before them have pointed out, significant effects from low power studies

1 will have exaggerated estimates of effects and could have the wrong sign of the effect. The
2 probability of the null hypothesis being true is not the only important issue in a statistical
3 test; accurate estimation of the parameter of interest and quantifying our uncertainty about
4 that estimate are equally important.

5 In summary, we investigated the intuitive belief held by some researchers that finding
6 a significant effect reduces the posterior probability of the null hypothesis to a low value.
7 We show that this intuition is not true in general. The common situation in psychology
8 and other areas is that the null hypothesis is a priori quite likely to be true. In such a
9 situation, contrary to intuition, finding a significant effect leaves us with much posterior
10 uncertainty about the null hypothesis being true. Obtaining a reasonable reduction in
11 uncertainty is thus another reason to adopt the recent recommendation by Benjamin et al.
12 (2018) to change Type I error to $\alpha = 0.005$. Furthermore, conducting high power studies is
13 an obvious but neglected remedy. Otherwise, the results will be indecisive.

14 Our key result is that the posterior probability for the null given a significant effect
15 varies widely across settings involving different Type I and Type II errors and different prior
16 probabilities for the null. The intuition that frequentist p-values may provide a shortcut to
17 this information is in general misleading.

23 Author contribution

24 SV had the idea for the paper. SV and DJS performed analyses. SV and DJS
25 generated the shiny app. SV and DJS wrote the paper.

Availability of simulations and computer code

All the computer code used for the simulations reported in the present manuscript, and the code for generating all Figures, will be freely available on-line at <https://osf.io/9g5bp/>. Moreover, we make a shiny app available at <https://danielschad.shinyapps.io/probnull/> that allows computing the posterior probability for the null given a significant effect for many different settings of Type I and II error and for different prior probabilities for the null.
